The RSGB Legacy Committee has funded a project to develop EMC analysis software tools for the EMC Committee to use when supporting Members. This article describes the state of play of the first stage of that work, a sophisticated tool to detect VDSL interference.

The EMC committee of the Radio Society of Great Britain has been monitoring sources of RFI for many years. A particular problem for HF communications is that the density of modern digital equipment in the home is ever increasing. In many cities it is now virtually impossible to receive any but the strongest HF transmissions.

It is normally assumed that, below 30MHz, testing for conducted emissions is sufficient to ensure compatibility. In the case of equipment that is not explicitly intended to transmit over air, it is further assumed that only the equipment and not its cabling needs testing. In the case of network ports this judgement appears to be based on the assumption that the cabling is able to carry the intended signals without excessive emission.

There are various Digital Subscriber Line (xDSL) standards in use in the UK. These range from ADSL1 using frequencies up to 1.1MHz through VDSL2 up to 17.664MHz in the UK, and a few installations of the new G.Fast that has versions that go up to hundreds of MHz.

Our investigations have shown that the biggest problem for HF communications at present is VDSL2. This has been difficult to prove as often VDSL2 broadband interference goes unrecognised since it looks like background noise. This is not surprising as any characteristic of a communication system that is distinguishable from white noise represents inefficiency in the use of the spectrum. Since VDSL2 is broadband and can approach the Shannon limit [1] over its entire bandwidth it is difficult to identify. This has, in the past, misled Ofcom into the conclusion that there is no problem with VDSL2 as all one sees is what looks like (elevated) background noise.

RFI survey setup
Measurements are typically made using a broadband magnetic loop such as a Wellbrook ALA1530 and the RF signals captured to a wave file (.wav) using a software defined radio (SDR). SDRs are used as they are commonly available and, with the correct processing, can produce good relative results. The sampling rates of the recording can be as low as 96kHz but 2MHz or more will produce clearer results provided the host PC doesn’t drop any samples. These wave files are then processed using the software Lelantos I have developed. This article explains how this is done and describes some of the key results.

How to detect VDSL2 RFI
To detect modern digital communications signals such as VDSL2 within an RF recording, one needs to understand the coding techniques used and any aspects of them that are less random. There are two key features of a VDSL2 signal that are not fully random. These are Sync symbols and the Cyclic Extension.

A VDSL2 system typically has 4096 carriers and has a typical symbol rate of 4000/second. Each symbol carries of the order 10,000 bits spread over the carriers. Of these symbols, 256 out of every 257 carry data. The 257th is the same structure but is a sync symbol. All these symbols appear random. The data symbols have been scrambled with a pseudo random sequence. However, the sync symbol is a fixed pseudo random sequence and is nominally the same every time. Thus if one can find this sync symbol one can in principle detect this within background noise and thus measure the strength of the VDSL2 signal relative to the noise. However, this signal is not strong, being only 1/257th of the total VDSL2 noise power.

Before anything else can be achieved one needs to align one’s measurement system, not only with the xDSL symbol rate but with its timing. An xDSL system starts up with a training phase during which timing parameters are exchanged and symbol alignment is established. This alignment is then maintained to high accuracy using digital phased locked loops relative to a crystal reference. It is not practical for a remote measurement system to obtain this information directly.

To obtain symbol alignment, one can make use of the second non-random feature of an xDSL system. This is the cyclic extension mechanism. This forms the core of the current measurement system as follows.

An introduction to cyclic extension
In any communication system that encodes data into symbols, a limiting
factor is inter symbol interference. This results from dispersion in the media such that signals arrive spread out in time relative to when they were transmitted. To avoid these signals impinging on the following symbol one needs to leave gaps between symbols to allow time for the transient response (‘ringing’ of the line) to die down. In an xDSL system, Discrete Multi-Tone (DMT) symbols are constructed using an Inverse Fast Fourier Transform (IFFT). For VDSL2 this typically generates 4096 carriers at 4.3125kHz spacing. The individual carriers are modulated with (scrambled) data using Quadrature Amplitude Modulation (QAM). Thus each individual symbol looks like a random mush with a potential frequency spectrum from DC to 4.3125kHz x 4096 = 17.664MHz (depending on which carriers are used). 17.664MHz is the top of Band Plan 998ADE17 as used by BT Infinity.

If the signal were to drop to zero immediately during the inter-symbol gaps this would cause distortion leading to inter channel interference. To avoid this, the symbols are extended and their envelopes smoothed to minimise harmonic distortion.

Figure 1 is derived from the freely available VDSL2 G.993.2 specification. In this figure N corresponds to the number of carriers. For a typical VDSL2 system this is 4096. The symbol generated by the complex IFFT will have 2N=8192 time domain samples (2N corresponds to the Nyquist rate). This is the un-extended symbol length. The diagram shows that part of the end of the DMT symbol is copied and appended to the beginning of the symbol as Lcp. Similarly part of the beginning of the DMT symbol is copied and appended to the end of the symbol as Lcs. Lcp and Lcs are the cyclic prefix and cyclic suffix.

In order to provide the smoothing of the envelopes Lcs and Lcp are overlapped during a period $\beta$. There is a gradual fade done during the period $\beta$ between one symbol and the next so there will be no noticeable join between symbols. (This contributes to the difficulty of detection without suitable software.)

The length of the cyclic extension CE is $Lcs + Lcp - \beta$. The VDSL2 specification allows for a varying length of CE and says that the duration of the overlap $\beta$ is vendor-dependant. The length of the CE is negotiated during initialisation of the xDSL line. It is exchanged during negotiation in units of (un-extended symbol length = $2N$) / 64. Though values from 2 to 16 are permitted, only support for the value 5 is mandatory. A value of 5 results in the usual symbol rate of 4000 symbols per second.

$$\frac{4.3125\text{kHz} \times \frac{64}{(64+5)}}{10^6} = 4000$$

This is the value used in practice everywhere.

### Detection of the cyclic extension

The cyclic extension provides us with both the symbol alignment information and a method of measuring the strength of the interfering xDSL signal.

To detect the cyclic extension in a signal from an SDR we need to do a correlation between the signal recorded by the SDR and a point on the same recording exactly one un-extended symbol period later, since the xDSL signals will be the same and genuine noise will not. To achieve this, we need to construct a digital delay of the correct duration.

Once we have this we need to do the correlation over a window of the length of the cyclic extension (CE). The un-extended
The symbol period is 1/4312.5 seconds = 231.884µs. The extended symbol period is 1/4000 = 250µs. Thus the length of the CE is 250 - 231.884 = 18.116µs.

Processing the signals from an SDR
On some common SDRs and, in particular, the FUNcube Dongle PRO+, the maximum sample rate is 192k of stereo signals (In phase and Quadrature) or equivalent to 384k combined sampling rate resulting in a 192k bandwidth. In terms of VDSL2, one un-extended symbol time = 231.884µs = 89.043 SDR samples at 384k. The correlation window = 18.116µs = 6.95 samples at 384k.

Producing the delay
For the rather common sampling rate of 192k stereo, 89,043 samples can be rounded to 89 – but that’s not a general solution for other sampling rates. An error of 0.043 samples corresponds to a phase error of about 8 degrees for the highest in band xDSL channel being measured (the Nyquist rate [2] being half the sample rate). That’s a fairly negligible error so on the early versions of the software this technique was used, and the error calibrated out. In the current version of Lelantos, a software filter is used to give the exact non-integral delay for whatever sampling rate is being processed.

The correlation
Once one has derived the direct and delayed samples the correlation itself is in principle straightforward. All that is required to achieve this is to multiply the direct samples with their corresponding delayed counterparts and sum them over the number of samples in the width of the CE.

Finding the symbol alignment
The outputs from the correlation are noisy. To overcome this Lelantos averages the results over many symbols. Since we don’t know the alignment yet Lelantos does this correlation for every possible symbol position. The position that emerges with the highest correlation is our correct alignment. However, there is an additional problem. The sampling rate of the SDR will not be perfectly calibrated relative to that of the VDSL2. When averaging over typically 10,000 symbols there will be alignment drift during the averaging process. To overcome this, Lelantos repeats the correlation for every possible phase alignment and also for errors in sampling rate from -25 parts per million (ppm) to +25ppm. It plots the variation in the highest correlation with sampling error in order to find the correct ppm error. Once it has determined this, it plots the variation in the correlation for different symbol alignments at the known ppm sampling error rate. The resulting graph should have clear peaks during the cyclic extension. Lelantos aligns the trace to show one symbol time with a CE peak at each end.

Measuring the ratio of VDSL2 noise to background noise
While doing the correlation just described, Lelantos also takes the squares of the samples, resulting in the RMS value of all signals. Once we know the symbol alignment we can square root both the correlation sum and the self product sum at the correct alignment. The ratio of the two is the ratio of the RMS values of the VDSL2 signal to the (VDSL2 + background noise) signal. Lelantos then calculates and reports the ratio of the RMS values of the VDSL2 signal to the other signals.
To check that the results are correct, Lelantos also contains a VDSL2 signal and noise generator. It can generate VDSL2 signals with any ratio of VDSL2 signal to other noise and with any VDSL2 ppm symbol rate error.

**Accuracy check**

To illustrate the Harmful Interference that the VDSL2 is generating we set up a second identical listening station in a farmer’s field outside the village. We then made simultaneous recordings in the amateur bands on both stations. Figure 9 shows a comparison of the signals recorded on the two stations on the 14MHz band. The red (‘here’) line shows the signals in the Member’s garden. The green (‘there’) line shows the signals in the farmer’s field. It is very clear that most of the signals seen in the field (green) are totally obstructed in the Member’s garden. One can in fact see the ripple in the red line corresponding to the 4.3125kHz VDSL2 channel spacing.
So…

Until JNT Labs suddenly gets back on form with RF or other radio-related hardware, or I get enough reader input (that’s you!), expect this column to move more towards SDR and DSP and software techniques. I’m doing the GNU Radio course running the day before the RSGB Convention in October, so hopefully that will inspire some ideas around existing low cost SDR hardware. At least, hopefully, it will make driving and using other people’s hardware with my own software and ideas that little bit easier.

[2] SRTM Height Data: The SRTM tiles of 1° squaroids can be found in the form of .ZIP compressed files at https://dds.cr.usgs.gov/srtm/version1/Eurasia/ for European locations, or https://dds.cr.usgs.gov/srtm/version1/ for an index into files for the whole world.
[3] The term Squaroid is used in place of the incorrect term ‘square’ here. The small subdivisions of Lat/Long are three-dimensional projections on a spheroid and are neither square, nor have their sides straight, nor at right angles. On a Mercator map projection they may appear rectangular, and at 60° latitude may even appear square but this is only an artefact of the projection in use. The term ‘squaroid’ removes this ambiguity.

VDSL2 signal characterisation continued from page 31

To make it clear that this ripple is indeed the VDSL2 channels, Figure 10 shows the spectrum of that spectrum. There is a very clear peak at 4.3125kHz marked with the blue line.

Summary
A software tool, Lelantos, has been developed that can be used to identify and measure the relative strengths and spectrum of VDSL2 RFI and desired signals. It can detect and compare the signals from multiple simultaneous VDSL2 lines. The tool also allows comparisons of recordings made at the same time, one being of the receiver obstructed by VDSL RFI and the other in a quiet environment close-by.

Conclusions
Surveys show that these results are typical for about half of those responding to the survey and are not just the result of unusual line faults. It is undeniable that VDSL2 is causing Harmful Interference in most areas of the country. This was predicted when the VDSL2 standard was developed and accordingly the standard mandates that the equipment can be configured to notch out 16 selectable frequency bands. The amateur radio bands for each region are listed in the standard as frequencies to be notched and it is left up to the operator to select the appropriate notches. In the UK no notches are being applied.

[1] The Shannon Limit of a communications channel is the theoretical maximum information transfer rate of the channel for a particular noise level.
[2] The Nyquist rate (or frequency) is named after electronic engineer Harry Nyquist. It is half of the sampling rate of a discrete signal processing system.

National Radio Centre

As you’ll read on pages 6 and 32, the RSGB National Radio Centre (NRC) at Bletchley Park is a fantastic success, attracting thousands of visitors each month and, often, many hundreds on a single day.

Alongside the history of radio, description of the spectrum, and hands-on displays for visitors, licensed radio amateurs will doubtless want to see the permanent special event station GB3RS. It’s a top-class installation with HF, VHF/UHF and satellite equipment, all set up to showcase the best of amateur radio and enthuse visitors with what they can do in the hobby. If you want to use the station, just bring along a copy of your licence and, time permitting, the volunteers will gladly let you have a go (and be there if you need any help).

The NRC is now open every day that Bletchley Park is open. It relies on a team of volunteers to greet and guide visitors, show them round, and generally engage about amateur radio. If you live within a reasonable distance and might be able to spare a day or two a month to help, please contact NRC Co-ordinator Martyn Baker, G0GMB, via email to nrc.support@rsgb.org.uk
